Introduction – Magnetron sputtering

Gudmundsson and Lundin (2020) in High Power Impulse Magnetron Sputtering Discharge, Elsevier, 2020

- Magnetron sputtering has been a highly successful technique that is essential in a number of industrial applications
- In a high power impulse magnetron sputtering (HiPIMS) the discharge is driven by high power pulses of low repetition frequency, and with low duty cycle
- This results in high discharge current density, increased electron density, and increased ionization of the sputtered species

Gudmundsson (2020) PSST **29** 113001

Introduction – Magnetron sputtering

Kateb et al. (2019) JVSTA **37** 031306

- For many applications a high degree of ionization of the sputtered vapor is desired
 - controlled ion bombardment of the growing film
 - ion energy – can be controlled by a negative bias applied to the substrate
 - collimation – enhanced step coverage
- Ionized flux of the sputtered material introduces an additional control parameter into the deposition process

Overview

- Thin film deposition
- The ionization region model (IRM)
- Deposition rate vs ionized flux fraction
- Working gas rarefaction
- Summary

Thin film deposition

Thin film deposition

- The film mass density is always higher when depositing with HiPIMS compared to dcMS at the same average power
- The surfaces are significantly smoother when depositing with HiPIMS compared to dcMS
- The films typically exhibit better crystallinity, and overall improved film properties
 - lower electrical resistivity
 - improved optical properties
 - improved mechanical properties
 - better oxidation resistance

From Samuelsson et al. (2010) SCT **202** 591

Thin film deposition

- TiN as diffusion barriers for interconnects
- HiPIMS deposited films have significantly lower resistivity than dcMS deposited films on SiO_2 at all growth temperatures due to reduced grain boundary scattering
- Thus, ultrathin continuous TiN films with superior electrical characteristics and high resistance towards oxidation can be obtained with HiPIMS at reduced temperatures

From Magnus et al. (2012) IEEE EDL **33** 1045

Thin film deposition

- There is a drawback
- The deposition rate is lower for HiPIMS when compared to dcMS operated at the same average power
- The HiPIMS deposition rates are typically in the range of 30 – 85% of the dcMS rates depending on target material
- Many of the ions of the target material are attracted back to the target surface by the cathode potential

From Samuelsson et al. (2010) SCT **202** 591

The ionization region model (IRM)

Ionization region model

- The ionization region model (IRM) is a time-dependent volume averaged plasma chemical model of the ionization region (IR) of the HiPIMS discharge
- The IRM gives the temporal evolution of the densities of ions, neutrals and electrons
- The IRM gives also two internal parameters that are of importance
 - α_t – ionization probability
 - β_t – back-attraction probability

Detailed model description is given in Huo et al. (2017) JPD **50** 354003

The definition of the volume covered by the IRM

- The IR is defined as an annular cylinder of width $w_{rt} = r_{c2} - r_{c1}$ and thickness $L = z_2 - z_1$, extends from z_1 to z_2 axially away from the target

Ionization region model

- The temporal development is defined by a set of ordinary differential equations giving the first time derivatives of
 - the electron energy
 - the particle densities for all the particles (except electrons)
- The species assumed in the non-reactive-IRM are
 - cold electrons e^C , hot electrons e^H
 - argon atoms $Ar(3s^23p^6)$, warm argon atoms in the ground state Ar^W , hot argon atoms in the ground state Ar^H , Ar^m ($1s_5$ and $1s_3$) (11.6 eV), argon ions Ar^+ (15.76 eV), doubly ionized argon ions Ar^{2+} (27.63 eV)
 - Metal atoms, sometimes metastable states, metal ion M^+ , and doubly ionized metal ions M^{2+}

Detailed model description is given in Huo et al. (2017), JPD **50** 354003

Ionization region model

- As an example the particle balance equation for the metal ion M^+ is

$$\begin{aligned}
 \frac{dn_{M^+}}{dt} = & \underbrace{k_{iz,M}^c n_e n_M + k_{iz,M}^h n_e n_M}_{\text{electron impact ionization}} + \underbrace{k_{P,iz} n_{Ar^m} n_M}_{\text{Penning ionization}} \\
 & + \underbrace{k_{chexc,1} n_M n_{Ar^+} + k_{chexc,2} n_{M^{2+}} n_{Ar}}_{\text{charge exchange}} - \underbrace{k_{iz,M^+}^c n_e n_{M^+} - k_{iz,M^+}^h n_e n_{M^+}}_{\text{electron impact ionization to create } M^{2+}} \\
 & - \underbrace{\frac{\Gamma_{M^+}^{RT} + \Gamma_{M^+}^{BP} (S_{IR} - S_{RT})}{V_{IR}}}_{\text{ion flux out of the ionization region}}
 \end{aligned}$$

Ionization region model

- The IRM is a semi-empirical discharge model and requires the measured discharge current and voltage waveforms
- The IRM has three unknown fitting parameters
 - the ion back-attraction probability for the metal ions $\beta_{t,pulse}$ and gas ions $\beta_{g,pulse}$
 - the potential drop across the IR $f = V_{IR}/V_D$
 - the electron recapture probability $r = 0.7$
- This leaves the $(\beta_{t,pulse}, f)$ parameter space to be explored through the model fitting procedure – the blue zones in the fitting map indicate the smallest mean square error

Ionization region model

- The ionization probability α_t increases with increased discharge voltage
- The peak discharge current increases with increased discharge voltage
- Earlier we have argued that the ionization probability depends only on the peak discharge current and increases with increased peak discharge current

Rudolph et al. (2022) JPD **55** 015202

- The back-attraction probability $\beta_{t,pulse}$ decreases with increased discharge voltage

A discharge with tungsten target

From Suresh Babu et al. (2022) PSST **31** 065009

Ionization region model

W: PSST (2022) **31** 065009

Cu: SCT (2022) **442** 128189

C: PSST (2021) **30** 115017

- The temporal evolution of the discharge current composition at the target surface for three different targets
- With Cu target Cu^+ ions dominate, with graphite target Ar^+ ions dominate

Deposition rate vs ionized flux fraction

Deposition rate – α_t and β_t

- We can relate the measured quantities normalized deposition rate $F_{DR,sput}$ and the ionized flux fraction $F_{ti,flux}$

$$F_{DR,sput} = \frac{\Gamma_{DR}}{\Gamma_0} = (1 - \alpha_t \beta_t)$$

$$F_{ti,flux} = \frac{\Gamma_{DR,ions}}{\Gamma_{DR,sput}} = \frac{\Gamma_0 \alpha_t (1 - \beta_t)}{\Gamma_0 (1 - \alpha_t \beta_t)} = \frac{\alpha_t (1 - \beta_t)}{(1 - \alpha_t \beta_t)}$$

to the internal parameters back attraction probability β_t

$$\beta_t = \frac{1 - F_{DR,sput}}{1 - F_{DR,sput}(1 - F_{ti,flux})}$$

and ionization probability α_t

$$\alpha_t = 1 - F_{DR,sput}(1 - F_{ti,flux})$$

Deposition rate – Optimization

- There are two measures of how good a HiPIMS discharge is:
 - the fraction $F_{DR,sput}$ of all the sputtered material that reaches the diffusion region (DR)
 - the fraction $F_{ti,flux}$ of ionized species in that flux
- There is a trade off between the goals of higher $F_{DR,sput}$ and higher $F_{ti,flux}$
- The question that remains:
 - How can we vary the ionization probability α_t and maybe more importantly the back-attraction probability β_t ?

Deposition rate – Optimization

- What determines the back-attraction probability ?
- How can one influence the back-attraction probability ?
- The back-attraction probability $\beta_{t,pulse}$, determined by IRM, versus the self-sputter yield for various target materials
- The data indicate that the back-attraction probability decreases roughly linearly with increased self-sputter yield

Working gas rarefaction

Working gas rarefaction

- The sputtered species enter the discharge at considerable energy, which is determined by the cohesive energy of the solid target
- The interaction between the energetic sputtered particles and the working gas atoms can lead to a reduction in the working gas density – as has been observed experimentally in the HiPIMS discharge
- The maximum in the degree of working gas rarefaction, determined by the IRM, for various target materials versus the peak discharge current density $J_{D,peak}$

From Barynova et al. to be submitted

Working gas rarefaction

- HiPIMS discharge with graphite target and $J_{D,peak} = 1 \text{ A cm}^{-2}$

Eliasson et al. (2021) PSST **30** 115017

- Argon atoms are lost mainly through electron impact ionization by primary and secondary electrons
- Contributions of kick-out and charge-exchange are negligible
- Diffusion contributes to a net loss of argon atoms during the pulse, but to a flow into the ionization region after the pulse is off

Working gas rarefaction

- HiPIMS discharge with copper target and $J_{D,peak} = 1 \text{ A cm}^{-2}$ at 0.5 Pa

Gudmundsson et al. (2022) SCT **442** 128189

- Argon atoms are lost mainly through kick-out by the sputtered species
- Electron impact ionization by primary and secondary electrons have smaller contributions

Working gas rarefaction

- HiPIMS discharge with tungsten target and $J_{D,peak} = 0.54 \text{ A cm}^{-3}$

Suresh Babu et al. (2022) PSST **31** 065009

- The main contributor to the loss of argon atoms from the IR is kick-out by tungsten atoms sputtered from the target
- The second most important loss process is electron impact ionization by secondary electrons followed by electron impact ionization by the primary electrons

Working gas rarefaction

- The relative contributions of the various processes to working gas rarefaction varies greatly depending on the target material
- The various contributions versus the atomic mass of the target material for $J_{D,peak} \sim 1 \text{ A/cm}^2$ and $p_g \sim 1 \text{ Pa}$
- Electron impact ionization by primary electrons is rather significant for a graphite target, but its role decreases with increased atomic mass
- The role of kick-out, or the sputter wind, increases with increased mass of the target atom

From Barynova et al. to be submitted

Summary

Summary

- The discharge current composition at the target surface depends on the target material
- There is an inescapable conflict between the goals of higher deposition rate and higher fraction of ionized species in the sputtered material flux
- The back-attraction probability appears to depend on the self-sputter yield – it is lower for higher self-sputter yield
- The main contributor to working gas rarefaction for low mass target atoms is electron impact ionization, while for heavy mass target atoms kick-out by the sputtered species is the main contributor
